Keywords: eukaryote, intron, computer analysis

1 Introduction

It is known that introns tend to be situated near the 5' end of genes in S. cerevisiae. Although it has been suggested that this locational bias may be related to the intron-loss process [2], the cause of the locational bias of introns is not yet clearly understood. One purpose of this work is to investigate whether a similar tendency of intron positions is observed in eucaryotes other than S. cerevisiae. We conducted comprehensive analyses on the locational distribution of all introns in seven species.

2 Methods and Results

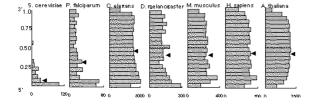

Figure 1: Intron distribution (all genes)

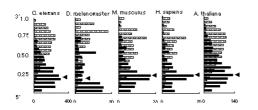

Figure 3: genes with two introns

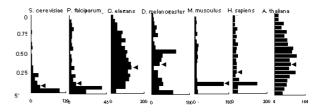

Figure 2: genes with one intron

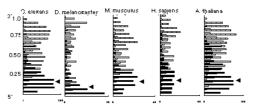

Figure 4: genes with three introns

The genome sequences of the following organisms were downloaded from the National Center for Biotechnology Information (NCBI) (ftp://ncbi.nlm.nih.gov/): S. cerevisiae, P. falciparum, C. elegans, D. melanogaster, M. musculus, H. sapiens, A. thaliana. We used Cleanup1.8.3 for the GenBank files in order to exclude redundant entries. Only introns located in coding regions were considered, and introns located in 5'or 3' untranslated regions are excluded from our analysis. Figure 1 shows the number of introns in each relative location for all of the seven species. The Y axis is the relative position within coding region, and the X axis is the number of introns located in the position. Triangles represent the median of all intron positions, showing the bias that more introns are located toward the 5' end of genes than expected. Figure 2 shows the result of the same analysis with genes containing only one intron. Comparatively, these single-intron genes show a stronger bias of intron positions. The results of analyses on genes with two and three introns are presented in Figures 3 and 4, respectively.

3 Discussion

From our results, it appears that first introns have a stronger tendency to be located towards the 5' end than do second or third introns. We also found, as shown in Figure 5, that first introns (the bottom) are on average longer than 2nd, 3rd, 4th, and 5th introns. It has been reported that certain genes have enhancer and silencer sequences within first introns, which may explain their longer length. If first introns contain signal sequences important for transcription initiation, it may be preferable for them to be located closer to the initiation sites. Genes coding ribosomal proteins often possess a single intron at the very beginning of their coding region. We compared these genes with homologous genes of other species. We found that many of the homologous genes also contain an intron at the beginning of their coding region. In summary, we found a strong indication that first introns have a special role in cellular metabolism and that this role may explain their longer length and the locational bias specific to them.
